WITH NO ATTACHED REGULATOR FOR THE POWER
SECTION, AND CORRESPONDING COMMUNICATION**

5

MODULE

FIELD OF THE INVENTION

The field of the invention is that of the design and manufacture of integrated circuits, e.g. of MOS type.

10

More specifically, the invention concerns the circuits delivering logic levels, whose voltage must remain constant even when the mains voltage varies.

BACKGROUND OF THE INVENTION

15

The invention concerns, in particular, the communication between two integrated circuits, e.g. via a USB connection. A USB buffer must in fact provide logic actions "1" and "0" at output, on a connection which can reach an output of 500 pF of capacitance, with a switching time of approximately 20 ns. The USB standard specifies that level "1" must have a voltage of 3V, whatever the mains voltage may be.

20

Normally, a USB buffer is just a power switch and is powered by a regulator delivering a constant 3V. This regulator must therefore have a very large output capacitor 15, in order to be able to support the peaks in current, in the region of 100

25

mA for 20 ns. In fact, it would not be able to react in 20 ns (as illustrated in Figure 2) without this capacitor, and the voltage would then drop greatly without the latter.

5 Figure 1 illustrates such a device. It therefore comprises a regulator 11, comprising an operational amplifier 111, which receives a V_{bgap} reference voltage on its positive terminal, for example, of 1.2 V. This operational amplifier 111 is
10 connected to a transistor 112, this latter looping back to the negative input of the former, via a resistor 113. This regulator therefore delivers a DC voltage of 3 V to be regulated, with the aid of the external capacitor 14, which is directed in
15 particular towards the buffer 12.

This buffer comprises two transistors 121 and 122, PMOS and NMOS respectively, which receive a command signal 123, and deliver on a resistor 124 the invention corresponding to the desired logic level.

20 As mentioned above, in order to obtain a response time below 20 ns, it is necessary to provide for an external capacitor 13, of a value of 500 pF for example. This necessitates providing for a specific output terminal on the integrated circuit,
25 in order to connect this external capacitor 13.

Furthermore, such a capacitor increases the cost of the assembly, as well as the space required and the complexity of assembly.

Moreover, a regulator, assuming the presence of an operational amplifier, leads to a significant crowding of the surface of the integrated circuit.

5 The objective of the invention is in particular to reduce these various difficulties with the state of the art.

More specifically, one objective of the invention is to produce an integrated circuit capable
10 of delivering a predetermined output voltage representative of a logic level, whatever the mains voltage, which does not require any external component, particularly a capacitor, to support peaks in current.

15 Another objective of the invention is to produce such an integrated circuit, which does not require the presence of a standard USB regulator, assuming the presence of an operational amplifier.

Another objective of the invention is to
20 produce such an integrated circuit, which allows for simplifying the design, manufacture and assembly of the integrated circuit.

In other words, one objective of the invention is to provide a simple and efficient
25 technique which uses little of the silicon surface, to produce such an integrated circuit.

The objective of the invention is also to produce such an integrated circuit, which offers a

very short rise time up to the desired voltage, e.g. in the region of 20 ns.

SUMMARY OF THE INVENTION

The invention therefore concerns an
5 integrated circuit comprising means of delivering a predetermined output voltage representative of a logic level to at least one output, the integrated circuit comprising means of distributing a mains voltage and means of generating an internal reference
10 voltage lower than the mains voltage.

Such a circuit comprises, in particular, means to connect the mains voltage to the output and means to limit and/or detect the voltage at the output at the value of the predetermined output
15 voltage, taking into account the reference voltage.

In this way, it is possible to obtain an accurate output voltage, whatever the variations in the mains voltage, without an external element such as a capacitor.

20 Advantageously, the predetermined voltage is equal to the reference voltage.

However, in another embodiment of the invention, it is possible to generate an output voltage which is different from the reference
25 voltage, while ensuring the same functionalities, by using for example, one or more transistors connected in series.

It is preferential that when the predetermined voltage is reached, the currents

circulating in the mains voltage connection means and in the means of limiting and/or detecting the voltage are balanced.

It is preferential that the connection
5 means comprise a first power transistor (TP0).

One benefit is that the drain from the first transistor is connected to the output and its source to the mains voltage.

One benefit is that the means of limiting
10 the voltage have at least a second transistor (TP1) controlled on its gate by the reference voltage.

It is preferential that the gate of the second transistor is connected to the gate of a third transistor (TP2) mounted in the diode at the
15 reference voltage.

It is preferential that the means of limiting the voltage comprise means to block the first transistor when the predetermined voltage is reached.

20 It is also preferential that the blocking means comprise first and second current mirrors (TN1/TN2, TP4/TP5) connected to each other.

One benefit is that the first current mirror delivers a blocking current when the
25 predetermined voltage is reached at the output, and in that the second mirror transmits a copy of the blocking current to the gate of the first transistor, in such a way as to block it.

One benefit is that the gate of the first transistor is connected to a control input via a fourth transistor (TN3).

Another benefit also is the size of the
5 third transistor is smaller than those of the transistors (TP4, TP5) of the second mirror, so that the latter imposes its level on the third transistor when it delivers the copy of the blocking current.

It is preferential that the output voltage
10 corresponds to the logic level "1" of a USB connection.

One benefit is that the reference voltage is used to control the CMOS logic section of the integrated circuit.

15 One benefit is that the reference voltage and/or the predetermined voltage give a value of 3 V, the mains voltage giving a value of 5 V.

The invention also concerns an integrated circuit communication module comprising means of
20 delivering, on at least one output, a predetermined output voltage representative of a logic level and an integrated circuit comprising means of distributing a mains voltage and means of generating an internal reference voltage lower than the mains voltage. One
25 benefit is that this module comprises means of connecting the mains voltage to the output and means of limiting voltage at the output at the predetermined output voltage value, taking into account the reference voltage.

BRIEF DESCRIPTION OF THE DRAWINGS

Other characteristics and advantages of the invention will be shown more clearly upon reading the following description of a preferred embodiment of the invention, given as a simple but not limiting illustrative example and some attached diagrams, among which:

Figure 1 is a diagram illustrating a regulating device according to the prior art with an external capacitor, referred to in the preamble;

Figure 2 illustrates the voltage of the output signal, according to both the prior art and the invention;

Figure 3 is a schematic diagram of the technique according to the invention;

Figure 4 is a detailed example of implementing the technique according to the invention;

Figures 5.a and 5.b illustrate value curves associated with the functioning of the device in Figure 4.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

The general principle of the invention consists in generating the 3 V voltage in the integrated circuit, without the need for a regulator for the power section. In general, there is in fact a regulator in the circuits for the CMOS logic section, so that it always operates at a low voltage (3 V and

not 5.5 V, to avoid the risk of destroying small transistors).

One beneficial aspect of the invention is that this 3 V voltage thus serves as the reference to generate a logic level "1", according to the USB standard (in the embodiment described), by taking the power directly from the 5 V supply. Figure 3 illustrates the general principle of the invention in a simplified way.

The system of the invention therefore includes means of connecting 31 the 5 V supply at the USB output. These connection means include, notably, a PMOS transistor, which connects the 5 V supply to the USB output.

Means of limiting 32 the voltage delivered to this USB output are provided for. They are connected to this output in such a way as to absorb part of the voltage, when necessary, so that it does not exceed 3 V.

These limiting means 32 simultaneously control the blocking means 33, comprising, for example, two current mirrors. They act on the connection means in such a way as to block the connection between the 5 V supply and the USB output.

So, it is possible to deliver a USB output at a regular 3 V voltage, without an external capacitor or an operational amplifier, or any other complex element.

Presentation of a particular method of carrying out
the invention

A particular example is now presented for implementing these techniques, with the help of
5 Figure 4, which shows a particular method of embodiment of the invention and Figure 5 (a and b) which illustrates some operational values.

The transistor TP0 (PMOS in this example, but it is of course possible to reverse the roles of
10 the PMOS and NMOS transistors) connects the 5 V supply AL5V to the USB output. It becomes active depending on the signal it receives at its gate, controlled as explained later.

According to the invention, the transistor
15 TP1 (PMOS) is connected to the USB output by its drain. Its gate is connected at a V_T voltage lower than the USB voltage (and with a value, for example, of approximately 2.2 V).

This V_T voltage can be produced using a
20 transistor TP2 of the same type as TP1, connected to diodes with a 3 V numeric voltage (always available in the CMOS logic section of an integrated circuit). This transistor therefore generates a voltage equal to $(3\text{ V} - V_T)$. This transistor TP1 thus has a
25 function of instant detector of level "1" (3 V) on the USB output. In fact, as soon as the voltage at the USB output exceeds 3 V, the voltage V_{GS1} of this transistor TP1 becomes greater than V_T (with a value of approximately 0.8 V) and therefore becomes active.

A current i passes through this transistor TP1. Due to this current i , the power transistor TP0 can be closed, using the blocking means, which connect the USB output to the 5 V supply. It is
5 therefore easy to limit the level "1" of the USB to 3 V.

A simple comparator comparing the USB output with the numeric 3 V voltage, to then close the power transistor TP0, would be too slow, and
10 would create overshoots and would also consume much. The solution, according to the invention, uses current mirrors in the blocking means and allows for efficiently reducing this disadvantage.

It should be noted that the principle
15 described above also works with NMOS transistors in place of the PMOS, TP0 and TP1 transistors.

Illustration of the functioning of the device in Figure 4

When a level "1" is wanted at the USB
20 output, the command DPLUS changes to "1" (51, Figure 5.a). The transistor TN3 then opens the power transistor TP0, by applying a VSS voltage to its gate. The voltage at the USB output then progressively rises (52, Figure 5.a). When it reaches
25 3 V, after about 20 ns (53, Figure 5.a), the transistor TP1 becomes slightly conducting, as its VGS1 voltage has become greater than the VT voltage. The current coming from the transistor TP0 to the transistor TP1 is then instantly re-copied by the

current mirror formed by the transistors TN1 and TN2, then by the current mirror formed by the transistors TP4/TP5.

5 So, when a current circulates in TP1, there is a similar current circulating in TP5. This current allows for closing the transistor TP0, by resetting its gate voltage to $5V - V_T$, which leads to its closure, at least partially.

10 The transistor TP5 is configured in such a way that it is able to impose its level on transistor TN3, the latter being a very weak transistor.

15 So, the system charges the USB capacity up to 3 V, and then maintains this level (54, Figure 5.a), by balancing the currents, in the region of a few dozen μA in the transistors TP0 and TP1. All the power to charge the 500 pF of the USB thus comes directly from the mains voltage AL5V (55, Figure 5.b). There is therefore no need for a USB regulator or external capacitor in the solution according to
20 the invention.

Applications

The device of the invention can be installed whenever external capacitors need to be reduced to a minimum, e.g. for USB connections. It
25 applies particularly in the case where the integrated circuit has an internal voltage reference has the same value as the voltage to be output, via buffers.

General

In one particular embodiment of the invention, one or more other transistors are used in series with the transistor TP2, or even a low-power
5 regulator (e.g. 1.2 V), so as to generate a USB output voltage (e.g. of 2 V) which is different from the reference voltage, while ensuring the same functionalities.

Although the present invention has been
10 described with reference to preferred embodiments, workers skilled in the art will recognize that changes may be made in form and detail without departing from the spirit and scope of the invention.
